1 Extended Experimental

This supplementary material provides extended experimental results to fully verify the performance and robustness of our method, including quantitative comparisons under two lighting conditions and qualitative visual comparisons.

1.1 Quantitative Comparisons Under Non-Uniform and Uniform Lighting Conditions

To comprehensively evaluate our method's performance across diverse lighting scenarios, we conduct experiments on the MipNeRF360-varying and LOM datasets — where each scene within both datasets is equipped with paired data under two distinct lighting conditions: non-uniform lighting (characterized by challenging varying exposure) and uniform lighting (corresponding to standard normal illumination). We compare our method with four state-of-the-art (SOTA) baselines: 3DGS (the foundational 3D Gaussian Splatting), Aleth-NeRF (which achieves illumination adaptation via a concealing field), GS-W (leveraging Gaussian feature decoupling), and Luminance-GS (adopting view-adaptive curve adjustment). For objective and comprehensive evaluation, we employ three core metrics: PSNR (assessing pixel-level fidelity, with higher values indicating better performance), SSIM (measuring structural consistency, with higher values being preferable), and LPIPS (evaluating subjective perceptual quality, where lower values reflect better perceptual realism). These metrics jointly capture each method's performance in both low-level pixel matching and high-level perceptual realism.

Scene	Metric	Non-Uniform Lighting					Uniform Lighting				
		3DGS	Aleth-NeRF	GS-W	Luminance-GS	Ours	3DGS	Aleth-NeRF	GS-W	Luminance-GS	Ours

Table 1: Quantitative Results on MipNeRF360-varying and LOM Dataset (Non-Uniform vs. Uniform Lighting). The best performance for each row is highlighted in red bold font.

Under non-uniform lighting conditions, our proposed method achieves optimal Structural Similarity Index Measure (SSIM) and Learned Perceptual Image Patch Similarity (LPIPS) across all 6 scenes, while securing the best Peak Signal-to-Noise Ratio (PSNR) in 3 scenes. This demonstrates the method's robust capability in handling illumination variations. Despite being tailored for non-uniform lighting scenarios, the proposed method still delivers State-of-the-Art (SOTA) performance under uniform lighting: it ranks first in SSIM across all scenes, secures the best PSNR in 5 scenes, and achieves the optimal LPIPS in 2 scenes. This verifies its strong generalizability without incurring performance trade-offs.

1.2 Qualitative comparison under normal and non-uniform illumination conditions

While objective quantitative metrics reflect overall method performance, qualitative visual comparisons more intuitively demonstrate the detail and perceptual quality of reconstructed images. We present visual comparisons of our method and baselines under uniform and non-uniform lighting to further validate our method's superiority.

Figure 1: Rendered Results of All Compared Methods on Test Images Under Uniform/Non-uniform Illumination

Taken together, the qualitative comparison results clearly demonstrate the superiority of our method under varying illumination conditions. Specifically, in non-uniform lighting scenarios, our results exhibit more natural color reproduction and richer, more complete object details and textures compared with other baseline methods. In uniform lighting scenarios, our method still delivers outstanding performance: for instance, the wall texture in the upper-right corner of the bike scene is rendered with finer details and higher fidelity to the real-world counterpart than that of the baseline methods. This indicates that our method can generate high-quality reconstruction results that are more consistent with real scenes, regardless of whether the environment is under complex or standard illumination.
